

## Chem 450 Exam 3

Name Key

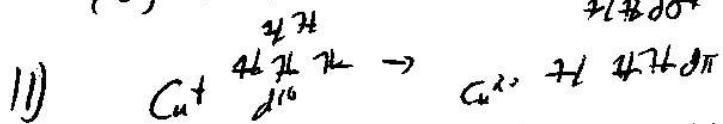

(1)(30 points) Place the following outer sphere electron transfer reactions in order from slowest to fastest. Explain your reasoning.

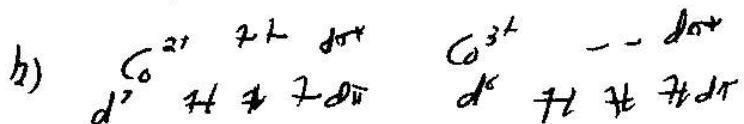

Factors that affect outer sphere e<sup>-</sup> transfer rate include

$\Delta G_{\text{ext}}$ ,  $\Delta G_{\text{inner}}^{\ddagger}$  +  $\Delta G_{\text{outer}}^{\ddagger}$ . Since  $\Delta G_{\text{ext}}$  is the same for all of these

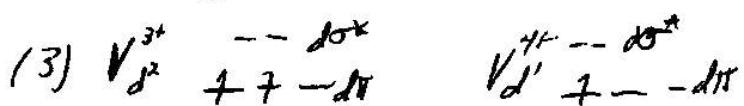

(1) the other 2 are the only factors.

This e<sup>-</sup> transfer results in the addition or removal of an e<sup>-</sup> from an antibonding orbital. This should result in a large  $\Delta G_{\text{inner}}^{\ddagger}$  (lots of bond length changes).

This e<sup>-</sup> transfer results in a high spin to low spin transition resulting in a change of 2 e<sup>-</sup> in the d<sup>10</sup>. This should have a very large  $\Delta G_{\text{inner}}^{\ddagger}$ .

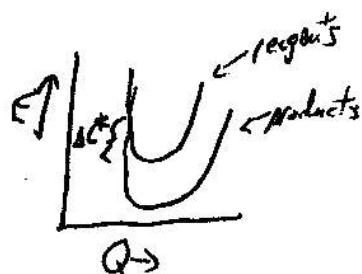

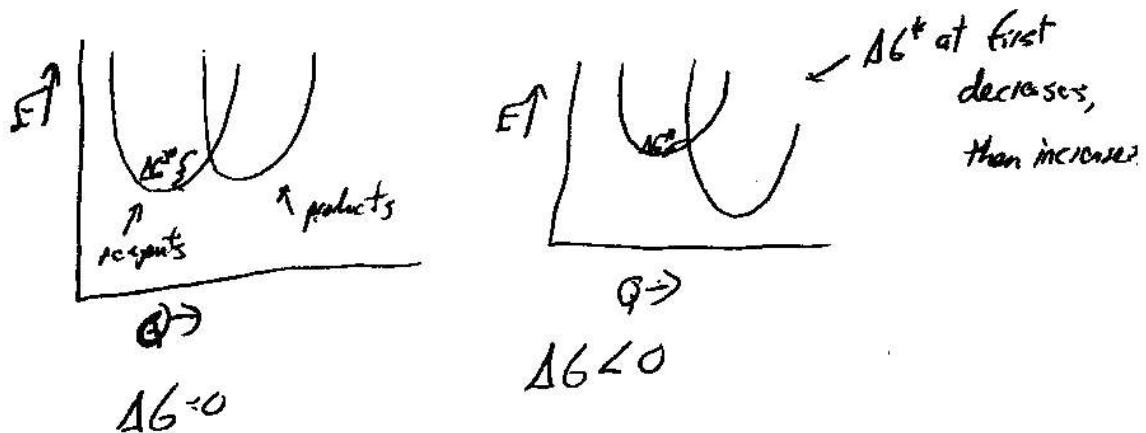

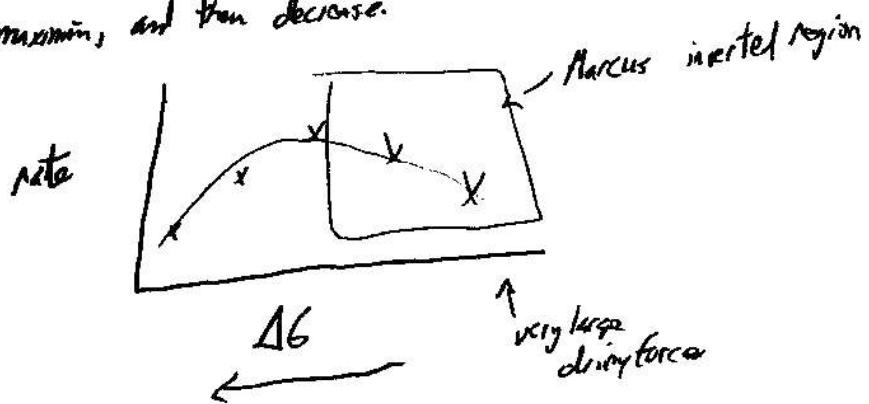

This changes the e<sup>-</sup> count in the d<sup>10</sup> (nonbonding) set only.

It should not result in much of a bond length change. Small  $\Delta G^{\ddagger}$ .

$$\boxed{\therefore 2 < 1 < 3}$$

(2)(20 points) What is the Marcus inverted region and under what conditions is it observed?

as  $\Delta G$  decreases, electron transfer rates increase, reach a maximum, and then decrease.

(3)(30 points) Use ligand field theory and hard and soft acid base theory (separately) to explain why CO binds well to low valent transition metals such as  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$  but do not bond well to high valent early transition metals such as  $\text{Sc}^{3+}$ . What type of bonding is this (explain with ionic/covalent and hard-soft acid base arguments)?

$$\text{CO}_n = 7.9 \quad \text{Fe}^{2+}_n = 7.3 \quad \text{Mn}^{2+}_n = 9.3$$

$$\text{Sc}^{3+}_n = 19.6$$

$\text{Sc}^{3+}$  is a hard acid,  $\text{Fe}^{2+}$  &  $\text{Mn}^{2+}$  are soft acids

CO is a soft base, so it should bind more strongly to the soft acids like  $\text{Fe}^{2+}$  &  $\text{Mn}^{2+}$  than the hard acids such as ~~like~~  $\text{Sc}^{3+}$ .

Soft acids & bases form covalent bonds well and hard acids & bases form strong ionic bonds.

CO will form covalent bonds (bind to soft acids).

High valent early transition metals have very few d-electrons (low C density) therefore backbond poorly. CO ~~COF~~ does not bond strongly to a metal unless it can backbond.

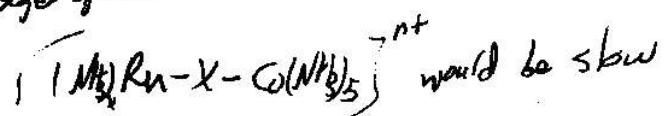

Metals such as  $\text{Fe}^{2+}$  &  $\text{Mn}^{2+}$  have quite a bit of d-electron density & can backbond well.

(4)(20 points) Do you think the following is an inner sphere or outer sphere electron transfer reaction? Explain your answer.

X	relative rate
$\text{Cl}^-$	4
$\text{CN}^-$	9
$\text{Ph}^-$	2
$\text{I}^-$	7

1)  $\text{Co}^{3+}$  is inert, it substitutes slowly, so the formation of a bridged species

2)  $\text{Ph}^-$  cannot bridge  $\text{Ph}-\text{O}-$ , and the rate of  $e^-$  transfer with  $\text{X}=\text{Ph}^-$  &  $\text{X}=\text{bridging ligands}$  is  $\sim$  the same.

It is outer sphere.

(6)(16 points) Which of the following are acids? Which are bases? Which definition(s) of acid or base apply(ies)?

(a)  $\text{Fe}^{2+}$  Acid, Lewis acid, Bronsted-Lowry acid

(b)  $\text{NH}_3$  Usenrich, Lewis, Brønsted-Lowry, Arrhenius base

(c)  $\text{SO}_3$  <sup>Usenrich</sup> Lux-Flood, Lewis acid

(d)  $\text{BF}_3$  Lewis Base, Usenrich base

(30 points) The outer sphere electron transfer reaction:

is 200 times faster than a similar outer sphere electron transfer reaction

Using the factors for the activation energy for the above reactions, explain this difference.

In both, the metal oxidation states are the same.

$$\Delta G^{\ddagger} = \Delta G_{\text{cavite}}^{\ddagger} + \Delta G_{\text{inner}}^{\ddagger} + \Delta G_{\text{ext.}}^{\ddagger}$$

Since the ox states are the same (+3/+2)  $\Delta G_{\text{cavite}}^{\ddagger}$  should be ~ the same

Since in both it is a  $\text{Ru}^{2+} \rightleftharpoons \text{Ru}^{3+}$  transition,  $\Delta G_{\text{inner}}^{\ddagger}$  should be similar.

$\text{Ru-NH}_3$  &  $\text{Ru-OH}_2$  groups should have a different interaction with the solvent, however.  $\text{OH}_2$  can act as both an H-bond donor & acceptor while  $\text{NH}_3$  can only be an acceptor as a ligand. It should take more energy to rearrange the  $[\text{Ru}(\text{H}_2\text{O})_6]^{2+}$  outer sphere interactions if  $\Delta G_{\text{outer}}^{\ddagger}$  should be higher  $[\text{Ru}(\text{H}_2\text{O})_6]^{2+}/3+$  rxn should be slower

Q) (20 points) Calculate  $k_{12}$  for the following reaction

Self-exchange rates for the oxidant and reductant are  $4.2 \text{ M}^{-1}\text{s}^{-1}$  and  $4000 \text{ M}^{-1}\text{s}^{-1}$ .  $K_{12} = 2.0 \times 10^{11}$  and  $f_{12} = 0.85$ .

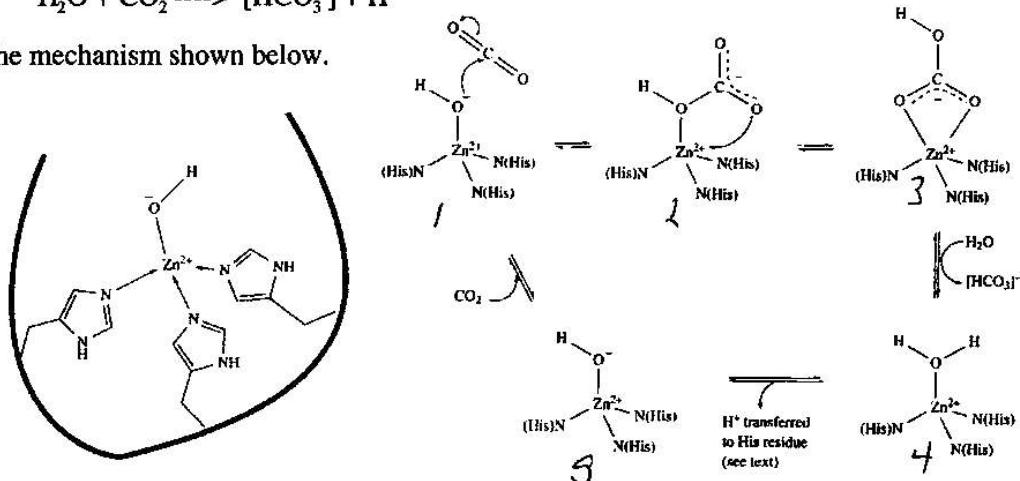

$$k_{12} = \sqrt{k_1 k_{22} K_{12} f_{12}}$$
$$k_{12} = \sqrt{(4.2 \text{ M}^{-1}\text{s}^{-1})(4000 \text{ M}^{-1}\text{s}^{-1})(2.0 \times 10^{11})(0.85)}$$

$$k_{12} = 5.34 \times 10^7 \text{ M}^{-1}\text{s}^{-1}$$

(9)(15 pts) Carbonic Anhydrase II catalyzes the reaction

by the mechanism shown below.

Count the electrons around the  $\text{Zn}^{2+}$  at each step in the cycle.  
Other  $2+$  metal ions can substitute for  $\text{Zn}^{2+}$  in these proteins, such as  $\text{Co}^{2+}$ . Why are high levels of many metals toxic?

$$(1) \quad \begin{array}{c} \text{Zn}^{2+} \quad 10e^- \\ | \quad \quad \quad | \\ 3\text{histidines} \quad 6e^- \\ | \quad \quad \quad | \\ 1\text{OH} \quad \underline{2e^-} \\ \hline 18e^- \end{array}$$

$$(2) \quad \begin{array}{c} \text{Zn}^{2+} \quad 18e^- \\ | \quad \quad \quad | \\ 3\text{His} \quad 6e^- \\ | \quad \quad \quad | \\ 1\text{OH} \quad \underline{\frac{2e^-}{18e^-}} \\ \hline \end{array} \quad (3) \quad \begin{array}{c} \text{Zn}^{2+} \quad 10e^- \\ | \quad \quad \quad | \\ 3\text{His} \quad 6e^- \\ | \quad \quad \quad | \\ \text{H}^+ \text{ transferred} \\ \text{to His residue} \\ (\text{see text}) \\ \hline \end{array}$$

$$(4) \quad \begin{array}{c} \text{Zn}^{2+} \quad 10e^- \\ | \quad \quad \quad | \\ 3\text{His} \quad 6e^- \\ | \quad \quad \quad | \\ 1\text{OH} \quad \underline{\frac{2e^-}{18e^-}} \\ \hline \end{array}$$

$$(5) \quad \begin{array}{c} \text{Zn}^{2+} \quad 10e^- \\ | \quad \quad \quad | \\ 3\text{His} \quad 6e^- \\ | \quad \quad \quad | \\ 1\text{OH} \quad \underline{\frac{2e^-}{18e^-}} \\ \hline \end{array}$$

Another metal would not allow this catalytic cycle to proceed. The  $e^-$  counts would not be right (not 18 for most species). For  $\text{Co}^{2+}$ , most of the electron counts would be  $15e^-$ , not good with backbonding imidazole groups

(10) Ferredoxins, Rubredoxins, and cytochromes are iron containing proteins that transfer electrons. Why are such a wide range of structures needed for electron transfer in living organisms? Why isn't a single electron transfer structure sufficient (hint: think of respiration and photosynthesis).

Electron transfer agents are needed with a wide range of potentials for e<sup>-</sup> cascades such as respiration.
